Decadal and centennial mean state changes in South American summer monsoon (SASM) precipitation during the last 2,300 years are detailed using an annually resolved authigenic calcite record of precipitation δ18O from a varved lake in the Central Peruvian Andes. This unique sediment record shows that δ18O peaked during the Medieval Climate Anomaly (MCA) from A.D. 900 to 1100, providing evidence that the SASM weakened considerably during this period. Minimum δ18O values occurred during the Little Ice Age (LIA) between A.D. 1400 and 1820, reflecting a prolonged intensification of the SASM that was regionally synchronous. After the LIA, δ18O increased rapidly, particularly during the current warm period (CWP; A.D. 1900 to present), indicating a return to reduced SASM precipitation that was more abrupt and sustained than the onset of the MCA. Diminished SASM precipitation during the MCA and CWP tracks reconstructed Northern Hemisphere and North Atlantic warming and a northward displacement of the Intertropical Convergence Zone (ITCZ) over the Atlantic, and likely the Pacific. Intensified SASM precipitation during the LIA follows reconstructed Northern Hemisphere and North Atlantic cooling, El Niño-like warming in the Pacific, and a southward displacement of the ITCZ over both oceans. These results suggest that SASM mean state changes are sensitive to ITCZ variability as mediated by Western Hemisphere tropical sea surface temperatures, particularly in the Atlantic. Continued Northern Hemisphere and North Atlantic warming may therefore help perpetuate the recent reductions in SASM precipitation that characterize the last 100 years, which would negatively impact Andean water resources.

Recent work documenting the timing and geographic patterns of sub-centennial-scale Asian (1) and African (2) monsoon variability has advanced our understanding of late Holocene Northern Hemisphere (NH) monsoon systems; however, our knowledge of Southern Hemisphere monsoon variability remains limited. This is particularly true for the South American summer monsoon (SASM), the largest monsoon system in the Southern Hemisphere. Documenting the timing, direction, and magnitude of decadal to centennial changes in the SASM in the past will help determine the causes and relative importance of factors that influence monsoons and ultimately improve our knowledge of the climate system.

Previous paleoclimate studies in tropical South America show that over millennial time scales orbitally driven latitudinal changes in the Intertropical Convergence Zone (ITCZ), tropical continental convection and North Atlantic sea surface temperatures (SST) play important roles in driving SASM fluctuations (3, 4). However, the paucity of high-resolution Holocene hydroclimate records from tropical South America has hindered an evaluation of the role of these processes on SASM variability at decadal to centennial time scales. Here, we present an annually resolved reconstruction of the isotopic composition of tropical South American precipitation as preserved in authigenic sedimentary calcite from Laguna Pumacocha, a varved alpine lake in the central Peruvian Andes. This unique archive documents subdecadal to centennial-scale variations in SASM precipitation over the last 2,300 years and provides insight into how this system responded to abrupt climate change during the late Holocene.

Study Site

Laguna Pumacocha is a small, high-altitude lake in the eastern Peruvian Andes set in a cirque basin at 4,300 m above sea level (asl) (10.70°S, 76.06°W) whose geological, morphological and limnological characteristics make it well-suited for archiving SASM variability in its sedimentary record (Fig. 1 and Fig. S1). The relatively small watershed has an area of only 1.7 km2 and is surrounded by headwalls that rise to nearly 4,600 m asl. Jurassic marine limestones of the Chambará Fm. comprise the underlying bedrock and supply significant quantities of dissolved HCO3− and Ca2+ to the lake, maintaining a surface pH of approximately 8, an average alkalinity of 161 mg/L HCO3− and saturation with respect to calcite throughout the year. Authigenic calcite comprises between 22 and 38% of the sediment by weight and is likely formed when enhanced biological productivity draws down dissolved CO2, increasing the lake’s alkalinity and pH and initiating calcite precipitation. Scanning electron microscope images of the Pumacocha sediments show that the calcite crystals are euhedral with no apparent contamination by detrital limestone (Fig. S2). This is likely because the lake is flanked on all sides by a broad marshy zone that acts as a natural sediment trap for allochthonous material that might otherwise be washed into the lake during storm events (Fig. S1).

The 23.5-m deep Pumacocha lake basin has a large volume (1.37 × 106 m3) despite its small surface area (0.09 km2) and is characterized by steeply sloping sides that drop off rapidly to a flat bottom (Fig. S1). These features contribute to water column stability, which results in permanent stratification and anoxic conditions below 8–12 m water depth. Persistent deepwater anoxia has resulted in the near perfect preservation of millimeter-scale couplets in the upper 176.2 cm of the 579.0-cm Holocene-length record (Fig. S2). These couplets are composed of sub-millimeter-scale laminations of authigenic calcite and diatom-rich organic matter.
manner and were identified as varves based on the agreement between couplet counts, $^{137}$Cs and accelerator mass spectrometry (AMS) $^{14}$C ages (Fig. 2 and Tables S1 and S2). The varves extend uninterrupted from A.D. 840 to 2007, providing strong temporal constraints on the Medieval Climate Anomaly (MCA), Little Ice Age (LIA), and current warm period (CWP) in the Pumacocha record and allowing comparison with other high-resolution paleoclimate reconstructions.

Results and Discussion

The following discussion documents the close relationship between oxygen isotope values in precipitation ($\delta^{18}$O$_{\text{precip}}$) and lake water ($\delta^{18}$O$_{\text{lw}}$) and sedimentary calcite ($\delta^{18}$O$_{\text{cal}}$) from Pumacocha. We show that Pumacocha $\delta^{18}$O$_{\text{lw}}$ reflects variability in $\delta^{18}$O$_{\text{precip}}$ and that this variability is recorded by the $\delta^{18}$O$_{\text{cal}}$ of authigenic calcite that is precipitated from the lake’s water column each year, forming an annually resolved sedimentary archive of SASM intensity. When compared with regional and global paleoclimate records, the Pumacocha $\delta^{18}$O$_{\text{cal}}$ record provides insight into SASM precipitation variability on subdecadal to centennial time scales and during abrupt late Holocene climate events, including the MCA, which is not well documented by the currently available paleoclimate records.

Hydrology and Hydrology and $\delta^{18}$O$_{\text{precip}}$- Pumacocha is the uppermost lake in a topographically isolated catchment with limited groundwater reserves and no fluvial input. As a result, the lake’s hydrologic mass balance is dominated by precipitation. Data from the closest weather station in Cerro de Pasco (10.68°S, 76.25°W; 4330 m asl) show that regional precipitation averages 1.000 mm yr$^{-1}$ with approximately 60% occurring between December and March during the monsoon season. From these data we estimate that precipitation over the Pumacocha watersheds averages approximately 1.67 x 10^6 mm yr$^{-1}$. This is approximately 23% greater than the total lake volume (1.36 x 10^6 m$^3$), thereby maintaining hydrologically open conditions and a surface water residence time of less than a year. As a result, the influence of evaporation on the lake’s hydrologic and isotopic mass balances is minimal, a point illustrated by $\delta^{18}$O and $\delta D$ measurements on 27 monthly lake water samples collected at Pumacocha between August 2006 and July 2008 (Fig. 3 and Fig. S3). These samples constrain a local meteoric water line (LMWL) that is offset from, but parallel to, the global meteoric water line (GMWL; Table S3). This indicates that the isotopic composition of the lake water reflects seasonal variation in $\delta^{18}$O$_{\text{precip}}$ free from the effects of evaporation. If Pumacocha surface waters were influenced by evaporation, they would plot along the local evaporation line (LEL), which is constrained by water samples from closed basin lakes in the region that are sensitive to evaporation (Fig. 3). This LEL is oblique to the GMWL and LMWL and intersects the LMWL at a $\delta^{18}$O value of $-13.60\%o$. Additional support for the limited role of evaporation is provided by the close agreement between annual mean $\delta^{18}$O$_{\text{lw}}$ ($-13.0\%o$) and modeled annual mean $\delta^{18}$O$_{\text{precip}}$ ($-12.9\%o\pm 1.5\%o$) at Pumacocha (Table S4; refs. 5, 6). These data support the contention that Pumacocha $\delta^{18}$O$_{\text{lw}}$ reflects $\delta^{18}$O$_{\text{precip}}$ and that other influences on $\delta^{18}$O$_{\text{lw}}$ are negligible. The monthly water samples also record a strong seasonal cycle,

Fig. 1. Map of South America showing the locations of records discussed in the text (CB, Cariaco Basin; CC, Cascayunga Cave; PC, Pumacocha; QIC, Quelccaya Ice 557 Cap). Regions with precipitation >200 mm during the austral summer (December–February) are colored. Precipitation maxima over the oceans are related to low-level convergence within the ITCZ and the South Atlantic Convergence Zone (SACZ). Those over South America are associated with the SASM.

Fig. 2. Age–depth relationships for the Pumacocha record over the last 2,300 years. The gray box demarcates the A.D. 1963 $^{137}$Cs peak. Varve ages are shown in black with the 1% cumulative error. AMS $^{14}$C ages are represented by gray circles with error bars. Radiocarbon ages that were reversed and excluded from the age model are shown with black circles and error bars. The age–depth model is based on the equation of a 4th order polynomial fit to the AMS $^{14}$C ages and anchored to the varve ages.

Fig. 3. (A) Surface water samples from Pumacocha (black circles) and regional hydrologically closed basin lakes (gray triangles). Pumacocha surface water samples plot along a LMWL (black line) that parallels the GMWL (dashed line). Regional lakes with closed basin hydrologies plot along a LEL (gray line), which is oblique to both the LMWL and the GMWL and intersects the LMWL at $-13.6\%$ $\delta^{18}$O (VSMOW; gray square). (B) Same as in A but expanded to illustrate seasonal isotopic variability in the Pumacocha surface water.
indicating that $\delta^{18}O_{\text{w}}$ responds rapidly to changes in $\delta^{18}O_{\text{precip}}$ and is sensitive to variations in $\delta^{18}O_{\text{cal}}$ (Fig. S3). No relationship was observed between $\delta^{18}O_{\text{w}}$ and air, or lake-surface temperature, which is consistent with work that shows the amount of precipitation and rainout along the trajectory of an air mass are the primary factors that determine $\delta^{18}O_{\text{precip}}$ (7).

**Pumacocha $\delta^{18}O_{\text{cal}}$ and $\delta^{18}O_{\text{precip}}$.** Modern limnological data from Pumacocha demonstrate a clear relationship among $\delta^{18}O_{\text{w}}$, $\delta^{18}O_{\text{cal}}$, and $\delta^{18}O_{\text{precip}}$. Authigenic calcite was collected from littoral vegetation at Pumacocha in August 2006 and May 2008, and from deepwater sediment traps deployed between August 2006 and May 2007. When converted to Vienna standard mean ocean water, the annual and three-year-average $\delta^{18}O_{\text{cal}}$ values are identical within error to measured mean annual $\delta^{18}O_{\text{w}}$ (Table S4). This indicates that the calcite is precipitated in isotopic equilibrium with Pumacocha lake water and that $\delta^{18}O_{\text{cal}}$ measurements can be used to reconstruct past $\delta^{18}O_{\text{w}}$ variability. Considering the evidence that $\delta^{18}O_{\text{w}}$ tracks $\delta^{18}O_{\text{precip}}$, the correspondence between $\delta^{18}O_{\text{w}}$ and $\delta^{18}O_{\text{cal}}$ supports using down-core $\delta^{18}O_{\text{cal}}$ measurements as a proxy for reconstructing $\delta^{18}O_{\text{precip}}$. Although we recognize that the links among $\delta^{18}O_{\text{cal}}$, $\delta^{18}O_{\text{w}}$, and $\delta^{18}O_{\text{precip}}$ are empirical, the modern observational data support this working model as a reasonable first-order approximation.

**Temperature Effect on Pumacocha $\delta^{18}O_{\text{cal}}$.** Modern limnological and paleoclimate data suggest that temperature has a minor influence on the integrated $\delta^{18}O_{\text{cal}}$ signal at Pumacocha. Sediment trap $\delta^{18}O_{\text{cal}}$ averaged $-12.8\%e$ and varied by $0.8\%e$, which is about twice that attributable to temperature-controlled fractionation during calcite formation. On longer time scales, $\delta^{18}O_{\text{cal}}$ varied by up to $2\%e$ between the LIA and CWP (Fig. 4A). Accounting for temperature-controlled oxygen isotope fractionation during the formation of precipitation from water vapor ($+0.6\%e\, \text{C}^{-1}$; ref. 8) and calcite from lake water ($-0.22\%e\, \text{C}^{-1}$; ref. 9), a $2\%e$ shift requires a $5.5\, ^\circ\text{C}$ temperature change. This far exceeds estimates of South American LIA cooling inferred from glacial equilibrium line altitude changes in Bolivia ($1.1$ to $1.2\, ^\circ\text{C}$; ref. 10) and lacustrine temperature reconstructions based on changes in lake productivity in central Chile ($0.7$ to $0.9\, ^\circ\text{C}$; ref. 11). Although a $0.7$ to $1.2\, ^\circ\text{C}$ cooling could account for $0.3$ to $0.5\%e$ ($15$ to $25\%e$) of the Pumacocha $\delta^{18}O_{\text{cal}}$ shift between the LIA and the CWP, the remaining variance is unexplained by temperature. These modern limnological and paleoclimate data suggest that temperature is, and has been, a minor influence on the integrated $\delta^{18}O_{\text{cal}}$ signal at Pumacocha and that $\delta^{18}O_{\text{cal}}$ variability is attributable to changes in the isotopic composition of precipitation.

**SASM Variability and $\delta^{18}O_{\text{precip}}$.** The principal control on $\delta^{18}O_{\text{precip}}$ over tropical South America is Raleigh-type fractionation during rainout (7). This is reflected by observations that show $\delta^{18}O_{\text{precip}}$ is more negative during the austral summer wet season, despite warmer temperatures, and more positive during the dry austral winter, when temperatures are generally cooler (12). There is, however, a slight offset of about $1$ to $2$ mo between the most intense precipitation and the most depleted $\delta^{18}O_{\text{precip}}$ at Pumacocha. Similar observations have been made in the Andes of Bolivia and attributed to rainout processes upstream over regions with slightly different precipitation seasonality (13). Hence $\delta^{18}O_{\text{cal}}$ is not simply a measure of precipitation amount at the site, but rather of the intensity of monsoon-related convective activity along the trajectory of an air mass (12–14). Year-to-year $\delta^{18}O_{\text{precip}}$ variability documented by observations, proxy data, and stable isotope-enabled global climate models show that $\delta^{18}O_{\text{precip}}$ is lower during intense monsoon seasons and vice versa (7). This isotopic response to monsoon variability is preserved and enhanced along an air mass trajectory, even if the precipitation signal at the site where stable isotopes are measured is not exactly the same as over the core region of convective activity, in this case the Amazon Basin (7). Hence the isotopic monsoon signal tends to be much more spatially coherent than monsoon precipitation, which is more strongly affected by microclimatic effects (14). This “isotopic memory” of an air mass and its influence on downstream $\delta^{18}O_{\text{cal}}$ records like the one from Pumacocha means that local $\delta^{18}O_{\text{cal}}$ records reflect large-scale changes in the intensity of the SASM (7). We therefore interpret $\delta^{18}O_{\text{cal}}$ from Pumacocha as a proxy for the intensity of monsoon precipitation upstream.

Modern interannual variations in SASM intensity are caused by a number of factors. Pacific SST anomalies associated with El Niño–Southern Oscillation (ENSO) play a primary role in modulating SASM variability through changes in the Hadley and Walker circulation over tropical South America and the Pacific (15, 16). Changes in tropical Atlantic SSTs have also been linked to interannual variations in SASM activity and drought conditions over the Amazon Basin (15, 17). Soil moisture provides an important land surface feedback that has been shown to affect SASM precipitation patterns (18). All these factors lead to distinct variations in SASM activity, only loosely coupled to ITCZ variations over the tropical oceans on interannual time scales. Over the tropical Andes, summer precipitation is predominantly modulated by eastern equatorial Pacific SST (15). Cooling in the eastern equatorial Pacific (e.g., La Niña events) typically leads to reduced meridional baroclinicity and anomalous upper-level easterly flow over the Andes, which enhances near-surface moisture influx from the Amazon Basin, and vice versa. Therefore, although the SASM moisture supply lies almost exclusively in the tropical Atlantic, perturbations in atmospheric circulation caused by SST anomalies in the tropical Pacific play an important role mediating the intensity of the SASM in general and over the tropical Andes in particular (15).

SASM variability is less well understood on decadal and longer time scales because limited instrumental data in the tropics complicates investigations of long-term trends. Nonetheless, observa-
tions show that Atlantic SST variations play a significant role modulating SASM variability on multidecadal time scales (19). Paleoclimate studies similarly suggest that the tropical Atlantic may have been an important factor driving tropical South American rainfall variability on longer time scales and during past periods with different climatic boundary conditions (20, 21).

**SASM Variability and Mean State Changes.** Using the empirical relationships among Pumacocha δ18Oprecip, δ18Ocal, and δ18Oice, and the documented close relationship between SASM intensity and δ18Ocal (7, 12), we interpret down-core variations in Pumacocha δ18Ocal as representative of the intensity of the SASM. Accordingly, high δ18Ocal is taken to reflect a less intense SASM, whereas lower δ18Ocal represents a more intense SASM.

The Pumacocha δ18Ocal record is characterized by considerable decadal-scale variability with three pronounced century-scale mean state changes during the MCA, LIA, and CWP, indicating major changes in the strength of the SASM (Fig. 4A). During the MCA, δ18Ocal increased between A.D. 900 and 1100 with two distinct decadal-scale peaks from A.D. 935 to 950 and A.D. 1000 to 1040, indicating considerable reductions in SASM intensity. Medieval aridity was followed by a prolonged decrease in δ18Ocal during the LIA starting as early as A.D. 1300, with minimum values between A.D. 1400 and 1820. This trend signifies the most dramatic increase in the strength of the SASM identified in the 2,300-year-long Pumacocha record. After A.D. 1820, δ18Ocal generally increased to the present, especially after A.D. 1900. Between A.D. 1908 and 2007, δ18Ocal increased from ~15.0‰ to ~12.9‰ per year at an average rate of 0.02‰ per year, which is the steepest and most rapid δ18Ocal rise in the 2,300-year-long Pumacocha record. This increase reflects a long-term reduction in the intensity of the SASM that is similar in magnitude to the MCA aridity, but with a more abrupt onset.

Comparison with other highly resolved paleoclimate records from tropical South America shows that SASM mean state changes captured by the Pumacocha δ18Ocal record were regional in scale with similar timing, direction, and magnitude. Specifically, the Pumacocha record tracks the 900-year-long Cariacu Cave δ18Ocal record (6.09°S, 77.23°W, 930 m asl), which is interpreted as a record of South American rainfall (Fig. 4B; ref. 22). The correspondence between these δ18O records during their common period from A.D. 1050 to 2006 is notable because Cariacu Cave is 3,400 m lower than Pumacocha and over 600 km to the north. Interestingly, the timing of mean state changes in the two records is nearly identical, although both the degree and magnitude of δ18O variability are more pronounced in the Pumacocha record. Their similarities, however, support our contention that the Pumacocha record reflects regional scale precipitation variability and provides supporting evidence that strengthening of the SASM during the LIA was not strictly an Andean response.

The Pumacocha δ18Oice record also shares many features with the annually resolved Quelccaya Ice Cap δ18O (δ18Oice) record, which is approximately 500 km southwest of Pumacocha (13.93°S, 70.83°W; 5670 m asl; Fig. 4C; ref. 23). The timing and direction of mean state changes in these records are similar during the LIA and CWP, although the Quelccaya ice core shows greater variability and slightly later minimum δ18Oice values during the LIA. The MCA is less pronounced in the Quelccaya δ18Oice record than in the Pumacocha δ18Oice record, although δ18Oice increased between A.D. 980 and 1100 with two peaks centered on A.D. 990 and 1080. It is not clear why the MCA is less evident at Quelccaya because, although considerably lower resolution (100 years per sample), tropical Andean ice cores from Nevado Huascaran (24) and Sajama (25) have broadly elevated δ18O from A.D. 900 to 1300 and A.D. 900 to 1500, respectively. Notably, the Quelccaya δ18Oice record has historically been interpreted as a paleo-temperature record, although a number of authors have noted that precipitation amount likely plays a major role driving δ18Oice variability (e.g., ref. 26). Because the Pumacocha and Cariacu Cave records reflect SASM precipitation variations, their similarities with Quelccaya are consistent with the notion that Rayleigh distillation during rainout in the SASM region strongly influences isotopic records of tropical precipitation.

The close agreement in the timing, direction, and magnitude of mean state changes in δ18O during the MCA, LIA, and CWP from lake sediment, speleothem, and ice core records supports the idea that a common large-scale mechanism influenced δ18O reaching these central Andean sites spanning 11° latitude and 4,740 m of elevation. Based on the work presented here, the most likely cause of these documented shifts in δ18Oprecip is a change in SASM intensity as all three sites receive the majority of their annual precipitation during the monsoon season.

We compared the Pumacocha δ18Ocal record to volcanic and solar radiative forcing (Fig. 5; e.g., 27, 28), reconstructed NH temperatures (29), variations in the latitude of the ITCZ (30, 31), and North Atlantic SST’s (32, 33) to help identify the relevant factors that contributed to decadal variability and mean state changes in the SASM during the MCA, LIA, and CWP (Fig. 5). North Atlantic SST’s are represented by the Mann et al. (32) reconstruction of SST from 60° N to the equator and 75.5° to 7.5° W and referred to generally as the North Atlantic. These variables were selected because numerous lines of evidence suggest that ocean–atmosphere processes, which are important drivers of modern SASM variability, contributed to past SASM changes.
Role in modulating SASM rainfall on decadal and longer

coupled tropical ocean

δ
-18Ocal record were coincident with NH temperature maxima during the MCA and CWP. Conversely, the SASM was stronger than at any other point in the last 2,300 years when NH temperatures were at a 2,000-year low during the LIA. A cooling of the Northern Hemisphere leads to a southward displacement of the ITCZ, as documented in modeling and paleoclimate studies because of adjustments in the Hadley circulation balancing the need for enhanced northward heat transport (29, 30, 33). Although the Atlantic ITCZ serves as the main moisture conduit for SASM precipitation over the continent (37), the SASM and the marine ITCZ are separate systems, only loosely connected on interannual time scales (38). The remarkable similarities between the Pumacocha δ18Ocal record and the reconstructions of both tropical SST’s and the latitude of the ITCZ (29), however, suggest that the coupled tropical ocean–atmosphere system plays an important role in modulating SASM rainfall on decadal and longer time scales. This relationship is particularly apparent during the MCA, LIA, and CWP.

Weakening of the SASM observed in the Pumacocha δ18Ocal record during the MCA is contemporaneous with generally elevated radiative forcing and warm NH temperatures (Fig. 5 A and B; ref. 29). At the same time, SST reconstructions from the North Atlantic show warmer, although variable, conditions (32, 33), whereas those from the equatorial Pacific indicate La Niña-like cooling (32). Although there is some debate regarding the tropical Pacific’s response to radiative forcing, the available data support the occurrence of prolonged La Niña-like conditions during the MCA. Warm North Atlantic and cool eastern equatorial Pacific SST’s, as suggested by the proxy data, would shift the latitude of the ITCZ northward over both ocean basins (39, 40). In line with this model, elevated titanium concentrations (% Ti) in marine sediments from the Cariaco Basin off the coast of Venezuela occurred when North Atlantic SST’s peaked during the MCA, suggesting that the Atlantic branch of the ITCZ was persistently northward when the North Atlantic was warm (Fig. 5; ref. 30). Consistent with an intensification of the SASM when the ITCZ is shifted southward, the Pumacocha record shows that the SASM was considerably reduced during the MCA when peak % Ti in the Cariaco Basin record indicates that the ITCZ was persistently northward. The similarities between these records suggests that the northward shift in the ITCZ in response to tropical North Atlantic warming and eastern equatorial Pacific cooling during the MCA contributed to a reduction in the intensity of the SASM.

During the LIA, the Pumacocha δ18Ocal record shows a strengthening of the SASM from A.D. 1400 to 1820 that was stronger than during any other period in the last 2,300 years. This strengthening occurred at the same time that diminished solar irradiance and elevated volcanism acted in concert to reduce radiative forcing and cool the NH (29, 35). Also during this interval, SST reconstructions show that the North Atlantic cooled (31) while the equatorial Pacific exhibited El Niño-like conditions (32). Proxy records of ITCZ variability from lakes in the western Pacific (31) and the Cariaco Basin (30) in the Atlantic indicate that the ITCZ was displaced considerably southward over both basins during the LIA (Fig. 5C). In the Atlantic, the southward displacement of the ITCZ displacement is consistent with climate model simulations that show that NH cooling during the LIA would lower North Atlantic SST’s and strengthen the northern branch of Hadley Cell circulation, shifting the Atlantic ITCZ southward (34). The southerly position of the ITCZ over the Pacific and Atlantic during the LIA is coincident with the prolonged maximum in SASM rainfall documented by the Pumacocha record. This suggests that NH cooling and adjustments in the position of the ITCZ were more important in determining the mean state of the SASM during the LIA than enhanced El Niño-like conditions in the Pacific, which on interannual time scales tend to reduce rainfall over much of the SASM domain.

Increasing δ18Ocal in the Pumacocha record after A.D. 1820 indicates a long-term weakening of the SASM, particularly after A.D. 1900. This reduction in SASM rainfall follows increases in radiative forcing (27), instrumental and reconstructed NH temperatures (29), and SST’s in the central equatorial Pacific and North Atlantic (32). These conditions are similar to those associated with weakening of the SASM during the MCA with the exception of apparent El Niño-like warming in the equatorial Pacific (32). The relationship between the Pumacocha record and reconstructed North Atlantic SST’s, evident even in the modern record, suggests that the weakened mean state of the SASM since the end of the LIA may be related to a northward shift in the Atlantic ITCZ in response to North Atlantic and NH warming.

Summary and Conclusions

The sedimentary δ18Ocal record from Laguna Pumacocha provides an annually resolved view of variations in the isotopic composition of precipitation over tropical South America during the last 2,300 years. Changes in δ18Oprecip inferred from δ18Ocal are attributed to variability in the intensity of SASM rainfall and show that the SASM experienced considerable variability at decadal scales with three pronounced century-scale mean state changes during the late Holocene: (i) a prolonged period of marked aridity during the MCA (A.D. 900–1100), (ii) a pronounced wet period during the LIA (A.D. 1400–1820), and (iii) an abrupt return to more arid conditions since A.D. 1900, a period characterized by the most significant and persistent positive δ18Ocal trend in the entire 2,300-year record. The timing and direction of the mean state changes identified in the Pumacocha δ18Ocal record are consistent with regional records from the Quelccaya Ice Cap and Cacayunga Cave, indicating that the Pumacocha record reflects large-scale trends in SASM rainfall, although the magnitude of variability within the lake sediment, ice, and speleothem records is quite different. Additionally, the similarities between these records supports recent work showing that rainfall variability is a major influence on isotopic records of tropical precipitation.

On decadal to century time scales, the Pumacocha δ18Ocal record tracks reconstructed NH temperatures, north Atlantic SST’s, and latitudinal variability in the ITCZ. This suggests that SASM intensity is sensitive, in part, to latitudinal changes in the ITCZ on multidecadal time scales, likely mediated by NH surface temperatures and tropical SST’s. This idea is consistent with modern studies that document a relationship between North Atlantic SST and Andean effective moisture on millennial time scales (3, 4) and modern studies suggesting a tropical Atlantic influence on SASM variability. Despite our improved understanding of SASM rainfall variability during the MCA, LIA, and CWP, climate modeling studies and additional paleoclimate records of ocean and atmospheric conditions are needed to better define the relationships between SASM rainfall and ocean–atmosphere variability during the late Holocene. The results presented here, however, suggest that continued warming in the NH and North Atlantic might contribute to further weakening of the SASM. This is consistent with the sharp, persistent drop in SASM rainfall indicated by the Pumacocha δ18Ocal record since A.D. 1900 and a long-term...
decrease in mean rainfall over the Amazon Basin during the instrumental period from A.D. 1975 to 2003 (41). Given the anticipated loss of many tropical Andean glaciers within the next 50 years (42), sustained reductions in SASM rainfall could negatively impact the availability of water resources in the Andes and along the arid Pacific coast.

Materials and Methods

Sediment Core Recovery. Sediment cores were retrieved from Pumacocha using a piston corer in 23.5-m water depth in June 2005 and August 2006. The composite 579.0-cm Holocene-length sediment record is comprised of successive overlapping 1-m-long drives. A network of freeze cores collected from the lake between 2006 and 2008 captured the undisturbed sediment-water interface (Table 55).

Age Control. Samples for 210Pb, 226Ra, and 137Cs were measured at approximately 1 cm intervals between 0.0 and 30.0 cm from freeze core D-08 by direct gamma counting using an EG & G Ortec GXL high purity germanium well detector (Fig. 54 and Table 52). Eighteen radiocarbon (14C) ages were determined by AMS on selected charcoal fragments (Table 51). The varve chronology is based on couplet counts from high-resolution digital images of freeze core B-08 and piston core C-06 to a depth of 103.5 cm. Four counts were performed on each core to ensure data quality and to derive an estimate of cumulative age error (1%).

Carbonate Sampling and Measurement. The uppermost 210 laminations were individually sampled from freeze cores B-08, B-07, and D-07 for carbonate isotope analysis. Piston cores C-06 and A-05 were sampled at 1-mm intervals. Samples were measured at the University of Arizona and the University of Pittsburgh. Results were calibrated to the standards NBS-19 and NBS-18 and are reported in conventional delta notation as the per mil (‰) deviation from Vienna Pee Dee Belemnite (VPDB) with 1σ precision of ±0.1‰ for δ18Ocalc and ±0.3‰ for δ13Ccal. Replicate sample measurements yielded an internal sample reproducibility of ±0.02‰ for δ18Ocalc and ±0.03‰ for δ13Ccal.
