Abstract

Brachiopods have been extensively used in paleoclimatic and paleoecological reconstructions, but their utility would greatly increase if paleoseasonality information could be obtained from their shells. Determining seasonal seawater temperature variations from fossil brachiopods requires knowledge of specimen ontogenetic ages, which is difficult to determine compared to other organisms secreting a shell by accretion. In this study, the combination of the spiral deviation methodology and chemical proxies is tested for determining specimen ontogenetic ages and paleoseasonality using two species of fossil brachiopods, *Laqueus rubellus* and *Terebratula terebratula*, of Pleistocene and Late Miocene age, respectively. Spiral deviations were obtained for *Laqueus* and *Terebratula* using an R program developed for modern taxa, and well-preserved shells were analyzed using oxygen isotopes and Mg/Ca ratios as chemical proxies for past seawater temperature. Results reveal that locations of spiral deviations on shells of *L. rubellus* displayed a strong direct relationship with Mg concentrations, and resulting Mg/Ca-derived paleotemperatures were seasonal. Conversely, specimens of *T. terebratula* did not show a consistently strong relationship between Mg concentrations and spiral deviations, although resulting paleotemperatures agreed with those from previous studies. Overall, the results from this study indicate that the spiral deviation methodology combined with chemical proxies presents great potential for utility in past seasonal seawater temperature reconstructions in pristinely preserved, biconvex fossil brachiopods.

1. Introduction

Brachiopods are excellent recorders of paleoecological and paleoclimatic information because they have a long geologic history, represent one location and water depth, are geographically widespread, have modern representatives, and have lived in a variety of marine habitats throughout the Phanerozoic (e.g.,

Brand et al., 2011, 2012; Ivany, 2012; Pérez-Huerta et al., 2014; Garbelli et al., in press). Brachiopods have been particularly useful in reconstructing past climatic conditions, in particular seawater temperature and ocean chemistry, because they precipitate calcite shells in oxygen isotopic equilibrium with ambient seawater, and these shells are very resistant to diagenesis (e.g., Carpenter and Lohmann, 1995; Geldern et al., 2006; Suan et al., 2008; Yamamoto et al., 2010; Brand et al., 2013). Additionally, Mg/Ca ratios have demonstrated great potential as a past seawater temperature proxy in the adult portions of modern brachiopod shells (Lee et al., 2004; Pérez-Huerta et al., 2008, 2014; Butler et al., 2015). Thus, brachiopods have been used extensively to reconstruct past seawater temperature changes at low resolution

E-mail addresses: jvclark@crimson.ua.edu (J.V. Clark), [\(A. Pérez-Huerta\)](mailto:aphuerta@ua.edu).

in temporal scales of thousands to millions of years over the geologic record (e.g., Veizer et al., 1986; Suan et al., 2008; Giles, 2012; Mii et al., 2012). Currently, fossil brachiopods are not considered ideal bioarchives for obtaining past seasonal seawater temperature variability because this determination requires knowledge of specimen ontogenetic ages, which are difficult to estimate in comparison to other organisms secreting carbonate shells (e.g., bivalve mollusks; Klein et al., 1996; Dettman et al., 1999; Surge et al., 2001; Ivany et al., 2004; Surge and Lohmann, 2008; among others). Thus, an accurate methodology that improves ontogenetic age determination would greatly expand the utility of brachiopods in paleoclimate research.

In modern taxa, ontogenetic ages and growth rates have been analyzed based on *in situ* shell measurements and population studies of living brachiopods, although these studies are sparse (e.g., Thayer, 1977; Curry, 1982). Growth rates have also been studied using approaches combining shell chemistry and growth lines (Barbin and Gaspard, 1995; Yamamoto et al., 2010), but both of these methods have associated problems that limit their effectiveness in fossils (see Pérez-Huerta et al., 2014 and references therein). Additionally, Roark et al. (2016) and Powell et al. (2009) attempted to investigate seasonality by analyzing the growth lines and shell chemistry of fossil brachiopods, but none of these studies analyzed shell morphometry. More recently, shell spiral deviations (SSD) have been used to determine ontogenetic ages of modern brachiopods, where deviations of the shell outline from a perfect logarithmic spiral represent changes in growth (Aldridge and Gaspard, 2011; Pérez-Huerta et al., 2014; Clark et al., 2015). The combination of SSD, other morphological approaches to shell growth, and chemical proxies for seawater temperature have been shown to be potentially more effective in determining ontogenetic ages as well as seasonality in modern brachiopod species (Pérez-Huerta et al., 2014; Butler et al., 2015). Approaches that combine shell chemistry and morphometry to investigate seasonality, however, have not yet been tested on fossil specimens. In this study, two fossil brachiopod species are analyzed by combining their spiral deviations (SSD) and chemical proxies for temperature ($\delta^{18}\text{O}$ and Mg/Ca ratios) to

determine whether shell spiral deviations are potentially useful in specimen ontogenetic age determinations and past seasonal seawater temperature reconstructions.

2. Materials and methodology

2.1. Sample information

The brachiopods analyzed in this work include specimens of the species *Laqueus rubellus* (Family Laqueidae) and *Terebratula terebratula* (Family Terebratulidae) (Fig. 1). These specimens were used to develop the R code for obtaining specimen ontogenetic ages of fossil brachiopod shells in Clark et al. (2015). Thus, sample collecting sites and geological context for both species is provided in Clark et al. (2015) and reiterated here to facilitate the understanding of the present contribution. Additionally, a description of ideal brachiopod specimens for spiral deviation analysis is included in Clark et al. (2015). Shell parameters (length, width, and thickness) and spiral deviations (Table 1) are determined for three complete specimens of each species, with larger specimens selectively chosen to maximize the shell growth record (see Pérez-Huerta et al., 2014; Clark et al., 2015). Both species possess biconvex shells without ornamentations, such as spines.

2.1.1. *Laqueus rubellus* (Sowerby, 1846)

Shells of *Laqueus* were collected from the Jizodo Formation (0.39 Ma) and the Yabu Formation (0.31 Ma) of the Shimosa Group in central Japan. The depositional environment of specimen collection is representative of a shallow embayment, known as the paleo-Tokyo Bay. More specifically, the Jizodo Formation contains facies associated to littoral and sub-littoral zones (Endo, 1987). Fossil specimens of this species were selected as a “control group” because equivalent modern individuals can be collected from the Sagami Bay at water depths between 70 and 90 m, and have been used to determine shell spiral deviations and seasonality (Pérez-Huerta et al., 2014).

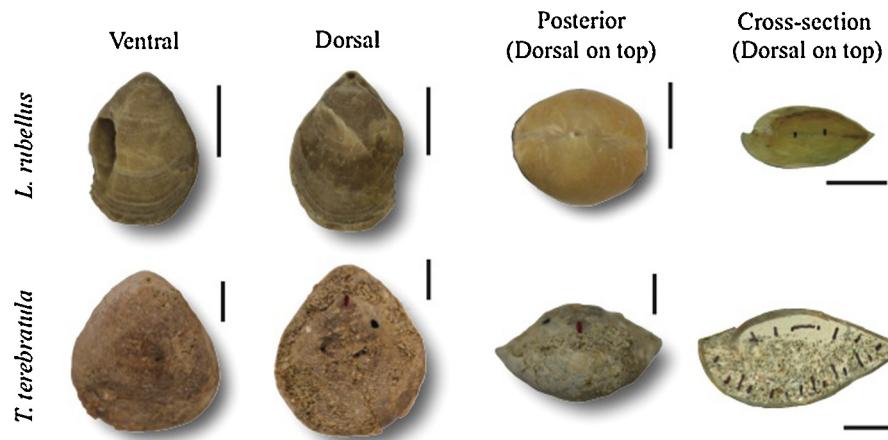

Fig. 1. Ventral, dorsal, posterior, and longitudinal-sectional views of the fossil brachiopods *Laqueus rubellus* and *Terebratula terebratula*. Scale bar = 1 cm. [Figure modified and adapted from fig. 1 in Clark et al. (2015), with permission from Palaeontologia Electronica (palaeo-electronica.org)].

Table 1

Size measurements (length, width, and thickness) and spiral deviations from all analyzed specimens of the species *Laqueus rubellus* and *Terebratula terebratula*. Modified after Clark et al. (2015).

Specimen	Length (mm)	Width (mm)	Thickness (mm)	Dorsal minima	Dorsal maxima	Ventral minima	Ventral maxima
<i>L. rubellus</i> 1	23.2	14.8	10.5	4	4	4	4
<i>L. rubellus</i> 2	29.3	19.0	17.0	2	3	3	3
<i>L. rubellus</i> 3	27.1	18.0	14.0	2	3	2	3
<i>T. terebratula</i> 1	47.3	34.0	24.5	5	6	3	4
<i>T. terebratula</i> 2	38.7	34.2	18.9	4	3	4	4
<i>T. terebratula</i> 3	40.4	32.0	21.9	4	4	3	4

2.1.2. *Terebratula terebratula* (Linnaeus, 1758)

Specimens were collected from the Tortonian (Upper Miocene) deposits of the Guadix Basin, a Neogene intra-mountain basin located in southern Spain, connected with the Atlantic Ocean through the Guadalquivir Basin. They correspond to accumulations in prodelta facies with an inferred depth around 30 m (see more details in Reolid et al., 2012).

2.2. Sample preparation

Samples had to be cleaned first to ensure that there was minimal unconsolidated material adhered onto the outside of the shells. Shells were then embedded in epoxy resin and cut with a Buehler Isomet 1000 Precision Saw along the plane of symmetry, producing two identical halves. The shell surface of each half was ground and polished with aluminum oxide (1.0 and 0.3 µm) until the surface was flat and free of scratches. These polished shell surfaces were used for determining shell spiral deviations and geochemical analyses. For more detail on sample preparation techniques, see Clark et al. (2015).

2.3. Spiral deviations

Both valves of each specimen were digitized using the image-digitization software, Vextrator 3.6.1 (available at <http://www.vextrasoft.com/download.htm>). Resulting (x, y) coordinates were imported into the computer program R (Gentleman and Ihaka, 1997), and previously developed R code was used to create spiral deviation graphs using the methodology discussed in detail in Clark et al. (2015) (Fig. 2).

2.4. Scanning electron microscopy (SEM)

One specimen within each species was analyzed to image its shell microstructure using a JEOL-7000 SEM instrument at the University of Alabama Central Analytical Facility (CAF) to assess preservation. Samples of the shell anterior region were etched with 2% hydrochloric acid for 20 s and coated with gold for 90 s using a sputter coater. Imaging was acquired at 30 keV, a current of 15 Ω, and a working distance of approximately 10 mm. Specimens were imaged at the anterior-most and posterior-most regions of each valve at various magnifications.

2.5. Electron backscatter diffraction (EBSD)

Highly-polished surfaces of the anterior-most region of a resin-embedded shell, which included both the dorsal and ventral valves, was cut to an approximate size of (1 × 2 × 0.5) cm in order to fit on the EBSD holder inside of the aforementioned SEM instrument. Samples were coated with a 2.5 nm thick coating of carbon using a Gatan model 681 high-resolution ion beam coater. The following SEM settings were used for EBSD analysis: voltage of 30 keV, current of 15 Ω, and a working distance of approximately 10 mm. The following EBSD settings were used during analysis: binning of 4 × 4, low gain, frame averaging of 1, and step size of approximately 1. Calcite was chosen as an identifying phase in all specimens. EBSD maps were created for dorsal and ventral valves of every specimen using AZtec 2.0 software, and then analyzed with EDAX OIM 5.3 processing software. EBSD data is represented by diffraction and crystallographic maps and pole figures are in reference to the {0001} plane of calcite (see Pérez-Huerta et al., 2014).

2.6. Magnesium analysis and Mg/Ca thermometry

In preparation for trace element analysis, sample cross-sections were marked with locations of spiral deviations. In order to do this, a biological outline with locations of deviations marked as red points was created using the R package (see Section 2.3). This graph was overlain on a high resolution image of the shell cross section on Adobe Illustrator, and this image was used as a reference when marking locations of spiral deviations on the shell cross section. Locations of spiral deviations were marked with a fine tipped needle on the resin immediately adjacent to the shell in cross sections. These marks were numbered on the resin in order to indicate which deviation it was and whether it was positive or negative (e.g., positive deviation closest to the umbo).

Samples were analyzed for Mg concentrations, using the isotope ²⁵Mg, on a laser ablation — inductively coupled plasma — mass spectrometer (LA-ICP-MS) at Union College in Schenectady, NY. In this analysis, a CETAC LSX-213 frequency quintupled Nd:YAG laser ($\lambda = 213$ nm) coupled to a Perkin Elmer Elan 6100 DRC ICP-MS was used according to methods stated in Gillikin and Dehairs (2013).

Daily performance tests were run every day prior to analysis using NIST 612 as a reference to ensure that ThO/Th values were

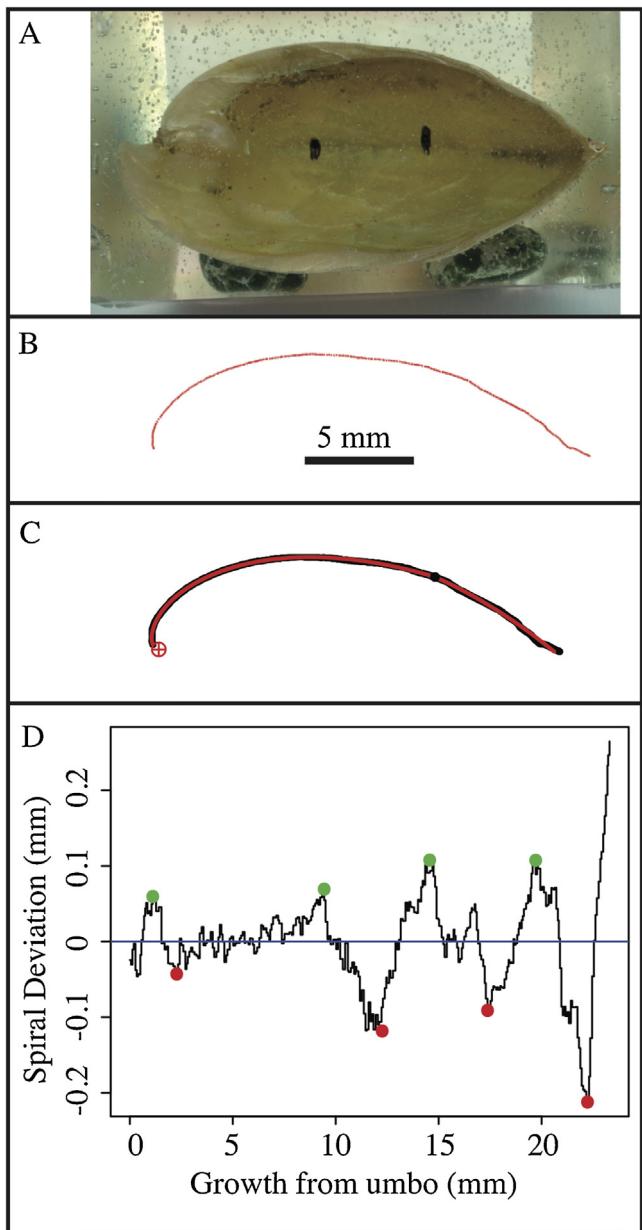

Fig. 2. Example of shell (*Laqueus rubellus*) digitization and spiral fitting. (A) The brachiopod shell was digitized by clicking the outline in an anterior-ward direction, starting at the umbo. (B) The digitized outline was saved as (x, y) coordinates, which were used to plot a biological outline in R. (C) R code was used to fit a perfect logarithmic spiral to the shell outline. (D) The deviations from a perfect spiral were represented in a spiral deviation graph, with green points representing spiral maxima and red points representing spiral minima. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

[Figure modified and adapted from fig. 3 in Clark et al. (2015), with permission from Palaeontologia Electronica (palaeo-electronica.org).]

less than 1% and Indium counts were above 25,000 counts/s. These values from the standard indicated that the instrument was running optimally and would produce reliable results. Standards were run at the start of each day and in between samples to allow for recalibration of samples as well as observation of daily instrumental drift. National Institute of Standards and Technology (NIST) 612 and NIST 610 were used as standard reference

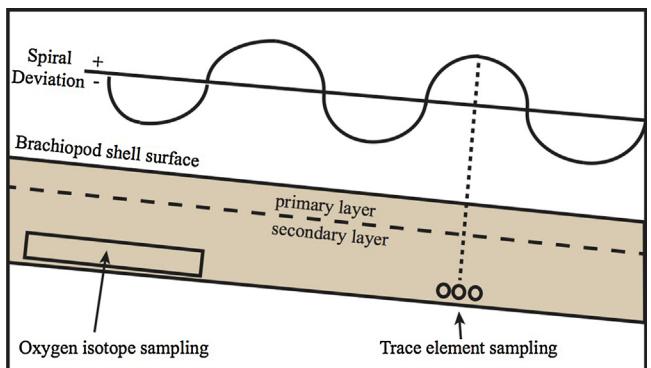

Fig. 3. Sampling methodology for oxygen isotope analysis using a micromill, and for trace (Mg) elements using a LA-ICP-MS.

material and the United States Geological Survey MACS-3 pressed carbonate standard (values from the USGS) was used as a reference sample. Brachiopod samples were analyzed using point analysis, a spot size of 50 μm , a laser energy of 100%, shot frequency of 10 Hz, shutter delay of 20 s, and a burst count of 600. Helium was used as the carrier gas (600 mL/min), which was mixed with argon after the ablation cell (840 mL/min).

Brachiopod specimens were analyzed at locations of deviations within the anterior regions, which had been marked prior to analysis (Fig. 3). Trace element sampling was done at locations in the innermost part of the shell within the secondary layer, which contains stable Mg concentrations representative of original seawater chemistry (Pérez-Huerta et al., 2008; Fig. 3). Additionally, one specimen within each species was analyzed at locations of spiral deviations in both the anterior and posterior regions. Each deviation location was analyzed at three spots, which were separated by approximately 50 μm (Fig. 3).

After analysis, elemental concentrations were calculated using GeoPro (CETAC) software. In this software, samples were corrected using the 20-s gas blank prior to each sample analysis when the shutter was closed. Samples were calibrated with NIST 612 and NIST 610 (values from Pearce et al., 1997), using ^{43}Ca as the internal standard. Elemental measurements were converted from signals in counts/second to concentrations in ppm. A detection limit was calculated for Mg by multiplying the standard deviation of NIST-612 blanks by 3. All analyses were well above the 13.79 ppm Mg detection limit. Standard deviations were calculated using MACS-3 elemental concentrations that were run over the course of the analyses; the mean relative standard deviation (%RSD) for ^{25}Mg was 4.32%.

The corrected Mg values as well as average Ca concentrations, which had been determined for each species using a Perkin Elmer Optima 3000 Dual View inductively coupled plasma-optical emission spectrometer (ICP-OES) at the University of Alabama (Ca = 375,000 ppm for *L. rubellus* and Ca = 368,000 ppm for *T. terebratula*), were used to calculate past seawater temperatures using the equation from Pérez-Huerta et al. (2008, 2014). Additionally, two Mg/Ca paleothermometry equations developed by Butler et al. (2015), based on the modern brachiopods *Terebratulina retusa* and *Liothyrella neozelanica*, were used as a comparison. The three temperatures at each deviation location were averaged and standard deviations

were calculated. These temperatures were compared to temperatures from previous studies as well as the resulting oxygen isotope paleotemperatures.

2.7. Oxygen isotope analysis and $\delta^{18}\text{O}$ thermometry

Samples were drilled with a New Wave micromill at the inner secondary layers of the shells, only at locations thick enough for sampling (Fig. 3). The inner secondary layer is precipitated in oxygen isotopic equilibrium with ambient seawater (Parkinson et al., 2005), and is therefore the most ideal sampling location. Sampling was done within the anterior regions of the shells, but the positions were not precisely homologous among samples. The purpose of this analysis was to determine if the Mg/Ca paleotemperatures were within the same range as the oxygen isotope paleotemperatures. By doing so, we hope to demonstrate the reliability of the calculated Mg/Ca paleotemperatures. The shell powder was placed on weighing paper and weighed on a Sartorius milligram scale until there was 50–100 µg of powder. The sample powder was then placed into 4 mL round-bottom glass vials, which were sealed to proper tightness. Five samples were taken from each valve of each fossil brachiopod specimen.

Fourteen vials in each analysis were allotted for the standard NBS-19, which was powdered using a mortar and pestle and measured into 50–100 µg aliquots. The sample vials were placed in a Thermo Gas Bench II, which maintained a temperature of 50 °C. Each sample vial was flushed with helium gas for 10 min. Each sample was then acidified with 100% orthophosphoric acid using a syringe in order to liberate CO₂ from the samples. The acidified samples were then analyzed in a Thermo Delta Plus continuous flow — isotope ratio mass spectrometer (CF-IRMS) at the University of Alabama Stable Isotope Laboratory for $\delta^{18}\text{O}$, using NBS-19 as a standard. Precision was better than 0.09‰ for oxygen.

Temperatures were calculated using resulting $\delta^{18}\text{O}$ values from the shells based on the equation of Epstein et al. (1953) modified by Anderson and Arthur (1983), which has also been used in previous studies on brachiopods by Curry and Fallick (2002) and Parkinson et al. (2005), with $\delta^{18}\text{O}_w$ in reference to VSMOW.

$$t(\text{°C}) = 16.0 - 4.14(\delta^{18}\text{O}_c - \delta^{18}\text{O}_w) + 0.13(\delta^{18}\text{O}_c - \delta^{18}\text{O}_w)^2$$

where $\delta^{18}\text{O}_c$ represents shell $\delta^{18}\text{O}$ values and $\delta^{18}\text{O}_w$ represents water $\delta^{18}\text{O}$ values. In this study, $\delta^{18}\text{O}_w$ was assumed to be 0 (‰ VSMOW) based on values used in previous studies involving samples from similar time periods (Williams et al., 2005; Findlater et al., 2014). The paleothermometry equation of Brand et al. (2013) was not used so that resulting temperatures were solely a reflection of oxygen isotopic composition, not magnesium composition.

3. Results

3.1. Spiral deviations

Spiral deviations generated from specimens of *L. rubellus* and *T. terebratula* were wide and large in magnitude

Table 2

Average $\delta^{18}\text{O}$ (‰ VSMOW) values and temperatures (°C) from the dorsal and ventral valves of *Laqueus rubellus* and *Terebratula terebratula*. T are temperatures resulting from the oxygen isotope thermometry equation of Epstein et al. (1953) modified by Anderson and Arthur (1983). $\delta^{18}\text{O}_w$ values are assumed to be 0 (‰ VSMOW) in *Laqueus rubellus* and *Terebratula terebratula*.

Specimen	$\delta^{18}\text{O}_{\text{Dorsal}}$	$\delta^{18}\text{O}_{\text{Ventral}}$	T _{Dorsal}	T _{Ventral}
<i>L. rubellus</i> 1	0.7 ± 0.2	0.7 ± 0.3	12.8 ± 0.8	12.9 ± 1.1
<i>L. rubellus</i> 2	0.8 ± 0.2	1.2 ± 0.2	12.5 ± 0.9	11.1 ± 0.7
<i>L. rubellus</i> 3	0.9 ± 0.4	1.3 ± 0.2	12.3 ± 1.5	10.5 ± 0.8
<i>T. terebratula</i> 1	-0.1 ± 0.6	0.1 ± 0.4	16.3 ± 2.5	15.7 ± 0.2
<i>T. terebratula</i> 2	-0.5 ± 0.6	-0.7 ± 0.5	18.2 ± 2.8	19.1 ± 2.3
<i>T. terebratula</i> 3	-0.8 ± 0.9	-0.7 ± 3.2	19.7 ± 4.0	19.4 ± 3.3

(Figs. S1 and S2). Shells of *L. rubellus* produced between three and four spiral maxima and minima per valve (Fig. S1) and between three and six spiral maxima and minima per valve for shells of *T. terebratula* (Fig. S2).

3.2. Shell preservation

In order to validate that the shell chemical data reflects primary signals, shells of both species were analyzed for preservation using SEM and EBSD analyses. SEM images of *L. rubellus* confirm that these shells are in pristine condition in terms of microstructure (Fig. 4). Well-preserved primary and secondary layers are recognized, with the latter consisting of both transversally and longitudinally cut fibers perforated by hollow punctae for both valves. EBSD analysis of the dorsal and ventral valves of *L. rubellus* specimens confirms exceptionally well-preserved shell material (Fig. 5). Secondary layer fibers contain calcite crystals with c-axes oriented perpendicular to the outer shell surface as in modern species (Cusack et al., 2008; Schmahl et al., 2012), and there is no evidence of recrystallization or secondary mineral phases.

SEM analysis of *T. terebratula* reveals the absence of a primary layer but the presence of a well-preserved fibrous secondary layer consisting of mostly transversally cut fibers (Fig. 6). Punctae are present across the whole shell thickness but seem to be filled with secondary calcite. EBSD analysis confirms the presence of a relatively well-preserved secondary layer, as observed in *L. rubellus*, and with punctae completely filled with small crystals of secondary calcite with multiple crystallographic orientations (Fig. 7).

3.3. Geochemical proxies and seawater temperature

3.3.1. $\delta^{18}\text{O}$ values

Average $\delta^{18}\text{O}$ values in specimens of *L. rubellus* ranged between 0.7 and 1.3‰ (VPDB), and values from the dorsal and ventral valves were within range of each other (Table 2). Resulting average paleotemperature estimates from both dorsal and ventral valves ranged between 10.5 °C and 12.9 °C (Table 2).

Average $\delta^{18}\text{O}$ values in specimens of *T. terebratula* ranged between -0.8 and 0.1‰ (VPDB), and values from the dorsal and ventral valves were within range of each other. Calculated temperatures ranged between 15.7 °C and 19.7 °C (Table 2).

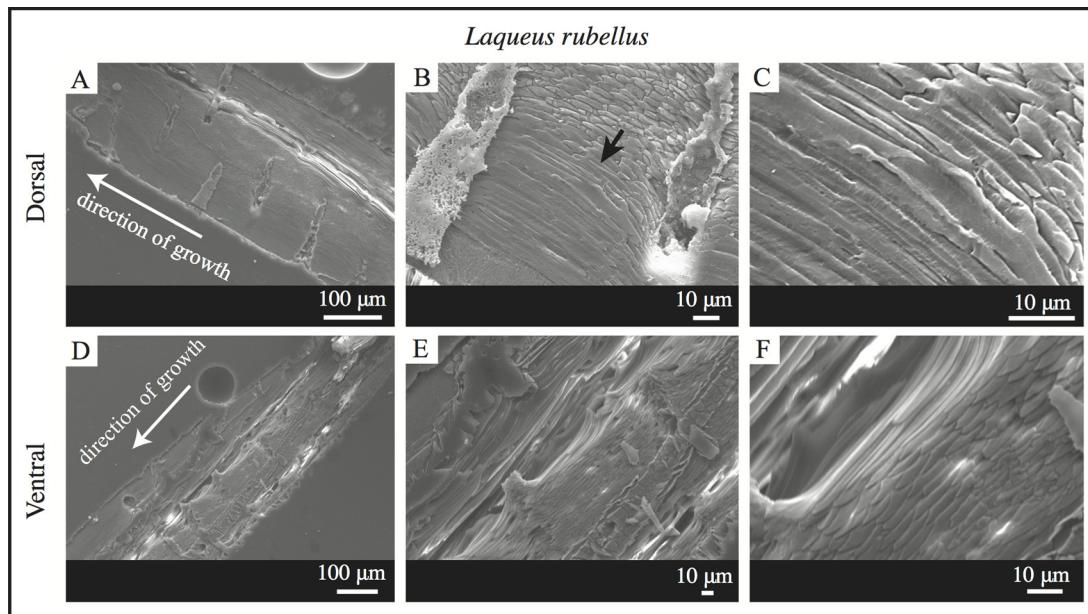

Fig. 4. SEM images of the dorsal and ventral valves of *Laqueus rubellus* 1. Note: Arrow in (B) points to the contact between transversely and longitudinally cut calcite fibers.

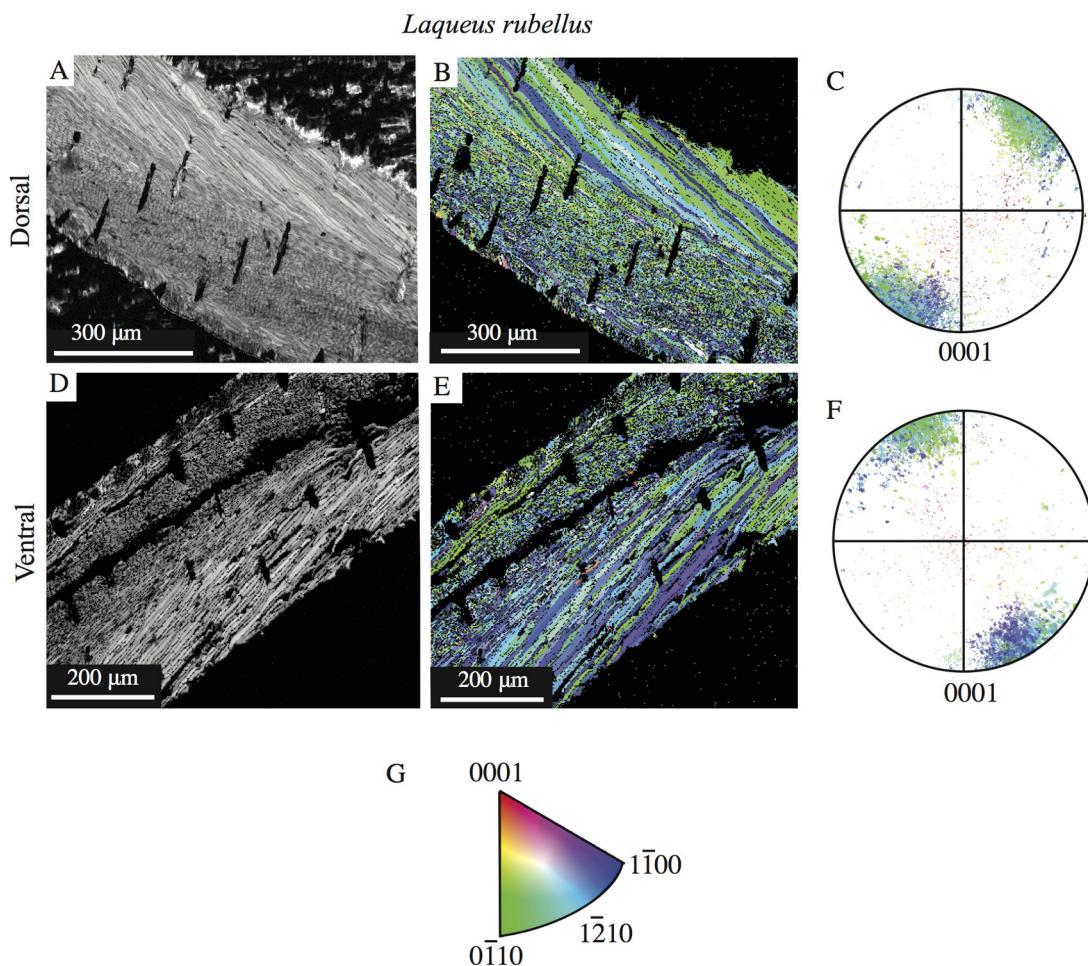

Fig. 5. EBSD data of the dorsal and ventral valves of *Laqueus rubellus* 1. (A and D) Diffraction maps; (B and E) crystallographic maps, with colors corresponding to the calcite crystallographic planes as represented in the color-key in G; (C and F) pole figures of crystallographic planes projected on the {0001} plane of calcite.

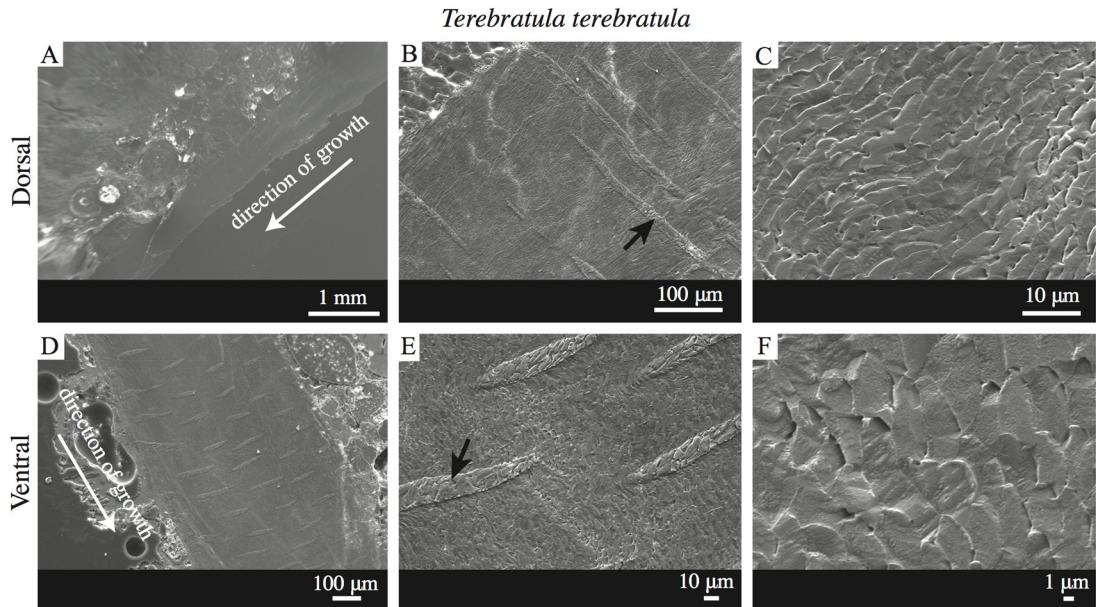

Fig. 6. SEM images of the dorsal and ventral valves of *Terebratula terebratula* 2. Note: Arrows points to punctae, which are in-filled with secondary calcite.

3.3.2. Mg/Ca

Average Mg/Ca values in specimens of *L. rubellus* ranged between 5.17 and 8.61 mmol/mol, and values from the dorsal and ventral valves were within range of each other (Table 3). Resulting temperatures ranged between 8.07 °C and 12.86 °C using the Mg/Ca thermometry equation by Pérez-Huerta et al. (2008), between 14.39 °C and 19.80 °C using the equation by

Butler et al. (2015) based on the modern brachiopod *T. retusa*, and between 6.02 °C and 9.02 °C using the equation by Butler et al. (2015) based on the modern brachiopod *L. neozelanica* (Table 3).

Average Mg/Ca values in specimens of *T. terebratula* ranged between 8.43 and 10.74 mmol/mol, and values from the dorsal and ventral valves were within range of each other (Table 3). For

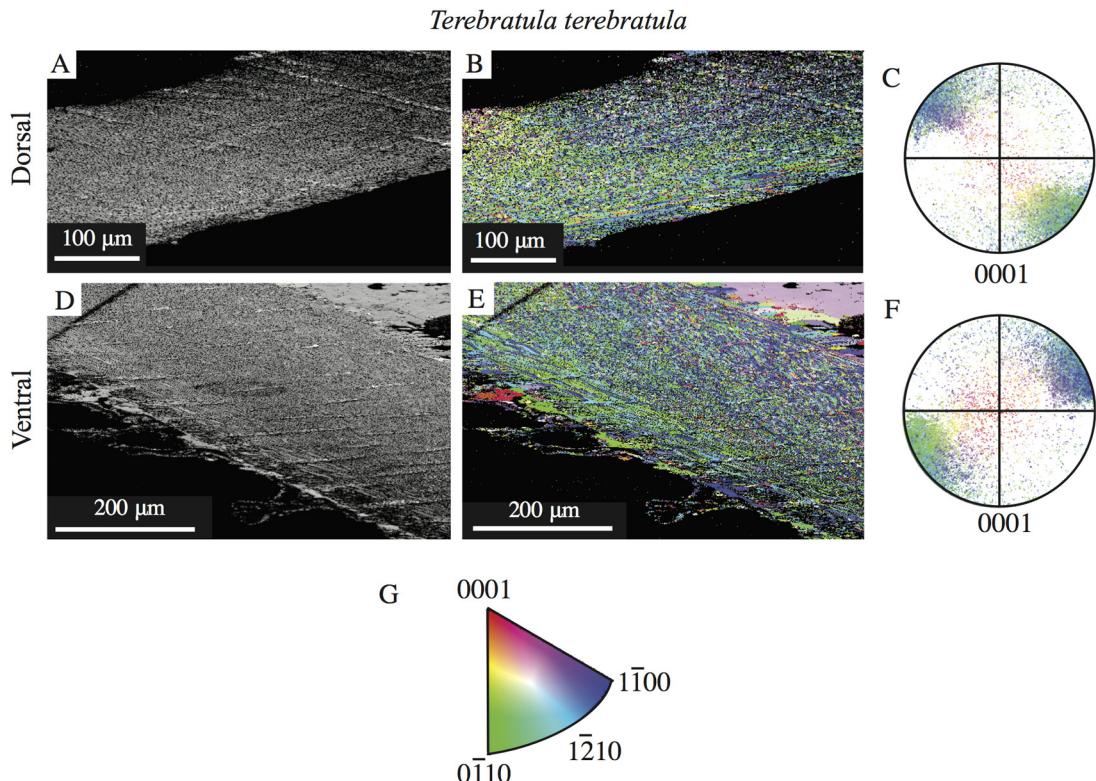

Fig. 7. EBSD data of the dorsal and ventral valves of *Terebratula terebratula* 1. (A and D) Diffraction maps; (B and E) crystallographic maps, with colors corresponding to the calcite crystallographic planes as represented in the color-key in G; (C and F) pole figures of crystallographic planes projected on the {0001} plane of calcite.

Table 3

Average Mg/Ca ratios (mmol/mol) and temperatures (°C) from the anterior regions of the dorsal and ventral valves of *Laqueus rubellus* and *Terebratula terebratula*. T¹ are temperatures resulting from the Mg/Ca paleothermometry equation by Pérez-Huerta et al. (2008) based on modern brachiopods, T² are temperatures resulting from the equation by Butler et al. (2015) based on the modern brachiopod *Terebratulina retusa*, and T³ are temperatures resulting from the equation by Butler et al. (2015) based on the modern brachiopod *Liothyrella neozelanica*.

Specimen	Mg/Ca _{Dorsal}	Mg/Ca _{Ventral}	T ¹ _{Dorsal}	T ¹ _{Ventral}	T ² _{Dorsal}	T ² _{Ventral}	T ³ _{Dorsal}	T ³ _{Ventral}
<i>L. rubellus</i> 1*	8.61 ± 3.05	7.77 ± 4.18	12.86 ± 4.12	11.72 ± 5.70	19.64 ± 3.21	17.58 ± 5.45	9.00 ± 2.01	7.91 ± 3.03
<i>L. rubellus</i> 2	8.49 ± 2.92	7.86 ± 3.25	12.67 ± 3.99	11.74 ± 4.52	19.66 ± 2.71	18.14 ± 4.71	8.97 ± 1.78	8.14 ± 2.81
<i>L. rubellus</i> 3	5.41 ± 1.59	5.17 ± 2.50	8.48 ± 2.17	8.07 ± 3.32	16.14 ± 2.35	14.39 ± 5.49	6.75 ± 1.41	6.02 ± 2.83
<i>T. terebratula</i> 1	8.43 ± 3.21	9.83 ± 1.46	11.58 ± 3.88	14.70 ± 1.10	19.52 ± 2.99	21.40 ± 0.87	8.89 ± 2.00	10.10 ± 0.61
<i>T. terebratula</i> 2	10.74 ± 2.64	10.06 ± 1.93	16.15 ± 3.49	14.41 ± 1.85	21.89 ± 1.83	21.12 ± 0.93	10.46 ± 1.27	9.91 ± 0.65
<i>T. terebratula</i> 3*	10.71 ± 2.84	9.33 ± 2.24	14.69 ± 4.45	14.18 ± 2.89	20.92 ± 2.48	20.86 ± 1.65	9.80 ± 1.69	9.74 ± 1.14

* Indicates that the posterior and anterior regions of the shell were analyzed for Mg/Ca ratios and temperatures.

temperature calculations, we used the same approach as for *L. rubellus*, and resulting temperatures ranged between 11.58 °C and 16.15 °C, 19.52 °C and 21.89 °C, and 8.89 °C and 10.46 °C (Table 3).

3.3.3. Mg/Ca ratios and spiral deviations

Mg/Ca ratios were compared to the locations of spiral deviations in *L. rubellus* and *T. terebratula* using the approach

described in Pérez-Huerta et al. (2014) (Figs. 8 and 9; Figs. S1 and S2). High Mg/Ca ratios were recorded at major spiral maxima and low Mg/Ca ratios were recorded at major spiral minima in the following deviation points of valves of *L. rubellus*: 1 dorsal, 2 dorsal, 2 ventral, 3 dorsal, 4 dorsal, 4 ventral, and 5 ventral (Table 4; Fig. 8; Fig. S1). Although the ventral valve of specimen 1 displayed a relationship between deviations and Mg/Ca ratios in the posterior region of the shell, it was not

observed as strongly in the anterior region. Using the equation by Pérez-Huerta et al. (2008), the average temperature variation between major maxima and minima in specimens of *L. rubellus* was 6.40 °C in 1 dorsal, 7.48 °C in 1 ventral, 9.74 °C in 2 dorsal, 9.20 °C in 2 ventral, 3.47 °C in 3 dorsal, 6.30 °C in 4 dorsal, 6.79 °C in 4 ventral, and 7.62 °C in 5 ventral. These variations were similar between valves of the same shell, although the variations were not consistent between shells. The temperature variations between major spiral maxima and minima ranged between 6.30 °C and 9.74 °C, except for 3 dorsal which had a lower variation of 3.47 °C. Spiral deviations that were interpreted to be the same in both valves did not consistently record the same temperature value, although this could be due to a slight offset in sampling locations (Table 4).

There was not a consistently strong relationship between Mg/Ca ratios and major spiral deviations in specimens of *T. terebratula* (Table 5; Fig. 9; Fig. S2). However, high Mg/Ca ratios were recorded at major spiral maxima and low Mg/Ca ratios were recorded at major spiral minima in the dorsal valve of specimen 1 and the ventral valve of specimen 3 (Table 5; Fig. 9; Fig. S2). Using the equation by Pérez-Huerta et al. (2008), the average temperature variation between major maxima and minima in the dorsal valve of specimen 1 was 7.46 °C and 3.91 °C in the ventral valve of specimen 3.

4. Discussion

4.1. Comparison of calculated temperatures based on Mg/Ca ratios and δ¹⁸O values

Average Mg/Ca based temperatures calculated from the dorsal and ventral valves of *L. rubellus* specimens strongly agreed with oxygen isotope derived temperatures recorded in the same shell when using the Mg/Ca thermometry equation of Pérez-Huerta et al. (2008) and the oxygen isotope paleothermometry equation of Anderson and Arthur (1983) (Tables 2 and 3). When using the equations based on *T. retusa* and *L. neozelanica* (Butler et al., 2015), resulting temperatures were significantly higher and lower than the oxygen isotope temperatures, respectively (Tables 2 and 3). This discrepancy shows that species-specific Mg/Ca paleothermometry equations do not produce reliable results when used on other species of brachiopods, possibly due to kinetic effects caused by different growth rates between species. However, it is important to note that there are other explanations for this discrepancy, including problems with assumptions regarding δ¹⁸O_w and habitat.

Average Mg/Ca based temperatures calculated from the dorsal and ventral valves of *T. terebratula* specimens, using the equation of Pérez-Huerta et al. (2008), were within range of the

oxygen isotope based temperatures (Tables 2 and 3). The Mg/Ca equation of Butler et al. (2015) based on *T. retusa* produced higher paleotemperatures than the equation of Pérez-Huerta et al. (2008), although these temperatures were also within range of the oxygen isotope based temperatures (Tables 2 and 3). However, the Mg/Ca paleothermometry equation of Butler et al. (2015) based on *L. neozelanica* produced significantly lower temperatures than those calculated using oxygen isotopes (Tables 2 and 3).

4.2. Comparison of calculated seawater temperatures with previous studies

The average Mg/Ca and oxygen isotope paleotemperatures recorded in specimens of *L. rubellus* ranged from 8.07 °C to 12.86 °C (using the equation after Pérez-Huerta et al. (2008)) and 10.5 °C to 12.9 °C ($\delta^{18}\text{O}$). These temperature ranges were both lower than those recorded in modern Sagami Bay, Japan, where these fossils originate. Temperatures were compared with modern seawater temperatures because of the lack of

paleoclimate data in this location from Pleistocene aged specimens. Seawater temperatures recorded between the years 1976 and 1980 at Sagami Bay at a depth of 75 m range from 13.12 °C to 21.34 °C (Pérez-Huerta et al., 2014). Mg/Ca and oxygen isotope paleotemperatures recorded in *L. rubellus* specimens were slightly cooler than modern seawater temperatures from the same location, but this was expected because of Pleistocene glaciation-inter-glaciation cycles (McClymont et al., 2013). During periods of glaciation, $\delta^{18}\text{O}_w$ is greater due to decreased evaporation and more saline seawater. Therefore, the actual Pleistocene paleotemperatures may be slightly greater than those calculated from oxygen isotopes using a $\delta^{18}\text{O}_w$ of 0‰ VSMOW.

The average Mg/Ca and oxygen isotope paleotemperatures recorded in specimens of *T. terebratula* ranged from 11.58 °C to 16.15 °C (using the equation after Pérez-Huerta et al. (2008)) and 15.7 °C to 19.7 °C ($\delta^{18}\text{O}$). These values were very similar to paleotemperatures reported from western Mediterranean sea surface during the Late Miocene, which was 16 °C to 19.5 °C in the same latitude according to Bosellini and Perrin (2008). During the Messinian the temperature ranges from 13 °C to

17 °C in the Sorbas Basin (south Spain) according to Sánchez-Almazo et al. (2001). However, these authors indicate a cooling of Mediterranean waters at the Tortonian–Messinian boundary as detected by $\delta^{18}\text{O}$ record of planktic and benthic foraminifera. The temperatures obtained from *Terebratula terebratula* of Guadix Basin fit fine with these previous proposals in spite of Guadix Basin was an intra-mountain basin really connected with Atlantic by the narrow straits and the Guadalquivir Basin (see Reolid et al., 2012).

4.3. Are spiral deviations the result of seasonal growth episodes?

Mg/Ca paleotemperatures resulting from specimens of *L. rubellus* produced seasonal variations at locations of spiral maxima and minima that agreed with seasonal seawater temperature data from a similar modern-day location, although the averages were slightly lower (Tables 3 and 4). These valve-average seasonal temperature variations, which ranged between 3.47 °C and 9.74 °C, were similar to seasonal seawater temperature variations recorded in modern Sagami Bay, which ranged from 3.40 °C to 8.22 °C between the years 1976 and 1980 (Pérez-Huerta et al., 2014). These seasonal variations were also consistent between dorsal and ventral valves within the same specimen (Table 4). However, temperatures recorded at spiral deviations on one valve did not necessarily match those of corresponding deviations on the opposite valve (Table 4). This discrepancy is likely caused by slight error in sampling locations of spiral deviations on the shell during the trace element analysis. Overall, based on the geochemical analyses, spiral deviations in specimens of *L. rubellus* are interpreted to be the result of seasonal growth episodes.

Within *T. terebratula*, a direct relationship between Mg concentrations and spiral deviations was apparent in the dorsal valve of specimen 1 and the ventral valve of specimen 3, although this relationship was not consistent in all specimens (Table 5). Using the equation by Pérez-Huerta et al. (2008), the dorsal valve of specimen 1 resulted in an average seasonal variation of 7.46 °C and the ventral valve of specimen 3 resulted in an average seasonal variation of 3.91 °C. The temperature variation recorded in the dorsal valve of specimen 1 was similar to modern day (8–9 °C) and Late Miocene (7.2 °C) seawater temperature variations reported in previous studies of the Mediterranean Sea (Brasseur et al., 1996; Poulos et al., 1997; Mertz-Kraus et al., 2009). Therefore, spiral deviations in the dorsal valve of specimen 1, and possibly those in the ventral valve of specimen 3, were interpreted as the result of seasonal growth episodes.

The absence of a relationship between spiral deviations and Mg concentrations in other specimens of *T. terebratula* could be attributed to major diagenetic alteration that has not been detected, although all paleotemperatures made biological sense for brachiopod survival and agreed with those from previous studies (Tables 3 and 5). The recrystallized punctae do not represent major diagenetic alteration because the vast majority of the shell is well preserved, but if the sampled material contained secondary calcite, this could alter the resulting Mg/Ca ratio and paleotemperature. Another potential explanation is that the

shape of shells within this species is not ideal for spiral deviation analysis with the currently developed spiral deviation R code. In the dorsal valves of *T. terebratula* specimens, there is a flattening in shell shape in the anterior region. Although a second perfect spiral was fit to the biological outline to account for this change in shell shape, there was a large spiral deviation at this location in all specimens, which did not correspond to changes in Mg concentrations. Additionally, the lack of relationship between Mg concentrations and spiral deviations could be caused by other factors that influence growth, such as spawning, environmental disturbances, or lack of food. These factors could potentially increase or decrease shell growth enough to produce spiral deviations not representative of seasonal growth episodes. Overall, spiral deviations in the dorsal valve of specimen 1 and the ventral valve of specimen 3 were potentially caused by seasonal growth episodes, but spiral deviations in the remaining specimens did not display a strong relationship between seasonality and spiral deviations.

4.4. Criteria for “true” spiral deviations and ontogenetic age determinations

The only species that demonstrated a consistently strong relationship between Mg concentrations and spiral deviations was *L. rubellus*. Criteria were defined for what constituted “true” spiral deviations that were due to seasonal growth episodes based on the results from the trace element analysis. Based on Mg concentration data from this study, a spiral deviation was deemed seasonal if it was above 0.05 mm in magnitude. Spiral deviations that did not exceed this value did not demonstrate a measurable change in Mg concentration. This criterion is similar to the value (0.025 mm) that was concluded in the study of spiral deviations in modern specimens of *L. rubellus* (Pérez-Huerta et al., 2014). Resulting ontogenetic ages were as follows: 4 years in specimen 1, 3 years in specimen 2, and 4 years in specimen 3. These ontogenetic ages were very similar to those predicted using growth rate studies of modern *L. rubellus* specimens (Yamamoto et al., 2010).

Within the species *T. terebratula*, only the dorsal valve of specimen 1 and the ventral valve of specimen 3 displayed a relationship between spiral deviations and Mg concentrations that was interpreted to be due to seasonal growth episodes (Table 5). Based on the trace element analysis, spiral deviations were considered seasonal in these valves if adjacent maxima and minima were both above 0.1 mm in magnitude. The dorsal valve of *T. terebratula* 1 resulted in an ontogenetic age of 4.5 years and the ventral valve of *T. terebratula* 3 resulted in an ontogenetic age of 4 years, which made biological sense based on their relative sizes and is plausible because the abundance of specimens over the age of five is less than one percent in other species of modern terebratulide brachiopods (e.g., Curry, 1982).

5. Conclusions

Two species of fossil brachiopods, including *Laqueus* and *Terebratula*, were analyzed to determine if the spiral deviation methodology combined with geochemical proxies is a valid

method of determining seasonal seawater temperature variations and ontogenetic ages in fossil specimens. Morphometric analyses revealed that spiral deviation patterns were wide and large in magnitude and produced ontogenetic ages that were plausible based on their relative sizes and previous growth rate studies. After determining that shells for both species were relatively well-preserved, a trace element analysis was done at locations of spiral deviations on the shells using LA-ICP-MS. The geochemical analyses revealed that spiral deviations were strongly related to Mg concentrations in specimens of *L. rubellus*, and resulting Mg/Ca paleotemperatures were seasonal. There was a direct relationship between spiral deviations and Mg concentrations in some specimens of *T. terebratula*, although the relationship was not consistent in all specimens. Paleotemperatures recorded in specimens of *T. terebratula* were within the predicted range. Overall, the results from this study indicate that the spiral deviation methodology combined with chemical proxies is a valid method of determining ontogenetic ages and past seasonal seawater temperatures in pristine fossil specimens of *L. rubellus* and presents great potential for use in other species of fossil brachiopods.
